A 32-year-old patient was evaluated for gastroesophageal reflux disease at our hospital, and laparoscopic Nissen fundoplication was performed. He was discharged 24 h later, with no complications. Seven days after surgery, he reported having progressive dysphagia and chest pain. Computed tomography scans of the thorax, abdomen and pelvis revealed a homogeneous collection measuring 40 × 32 mm in the thickness of the gastric wall (Fig. 1). Upper gastrointestinal endoscopy showed a subepithelial collection in the area of the fundoplication (Fig. 2).

After treatment with corticosteroids, the patient evolved favorably and was discharged 24 h later, showing good tolerance to a liquid diet.

Hematoma is a rare complication of Nissen fundoplication that should be included in the differential diagnosis of a recently operated patient with dysphagia.
