Quality-of-life

ABSTRACT

Background: Obesity is associated with reduced quality-of-life (QoL), which generally improves after bariatric surgery. The differential effect of each type of surgery (gastric sleeve [SG] and gastric bypass [RYGB]) on QoL is not yet fully understood.

Objectives: To understand which of these surgeries offers greatest improvement in QoL and patient satisfaction.

Methods: Systematic literature search on Pubmed in July 2014. Relevant articles were selected in a step-wise approach. The 2482 titles were scanned for relevance and 191 were selected for abstract reviewing; and 88 papers were selected for full text analysis.

Results: Only 5 papers compared the 2 techniques and only 17 more had retrievable data either on SG or RYGB. The reports were very heterogeneous, preventing a direct comparison of patient reported outcomes (PRO) among studies.

Improved results have been reported as early as 3 months and SF-36 scores were improved in all domains in medium to long-term. The question remains whether the improvement in QoL is related to the weight loss and which factors are associated with improved patients' perceptions.

Conclusions: There is wide heterogeneity in the reporting of PRO measures after bariatric surgery, but data is consistent with a significant improvement after both surgeries.

Larger and better-designed studies are required to understand if there are significant differences in the quality of life after SG or RYGB.

Introduction

The worldwide epidemic of obesity, fueled by a sedentary lifestyle and an energetically dense diet, has contributed to an unprecedented event in the history of mankind: for the first time, the number of obese people is greater than the number of undernourished.¹ Obesity is a growing public health concern in developed countries, and it is estimated that there are over than 1.5 billion obese people worldwide.² This represents about 5% of all the health related expenditures in the USA³ and leads to a significant decrease in life expectancy.⁴

Bariatric surgery is the most effective available treatment and the one that allows more significant and durable weight loss.⁵ It leads to reversal of co-morbidities and components of

the metabolic syndrome,^{6–10} as well as a reduction in all-cause mortality^{6–14} by as much as 89%.¹⁵ Its cost-effectiveness has been widely reported, and we conducted a cost-utility study based on a Markov model that concluded that RYGB is a cost-saving strategy.¹⁶

However, up to 18% of patients fail to achieve a body mass index (BMI) < 35 kg/m², and unsuccessful weight loss has been reported in 10–30% of patients who have undergone bariatric surgery.¹⁷

Roux-en-Y gastric bypass (RYGB) was one of the first approved surgical options for morbid obesity. In 1991 the National Institutes of Health (NIH) determined that RYGB was indicated for patients with a BMI greater than 35 with obesity related comorbidities and for patients with BMI greater than 40 without comorbidities.¹⁸

Since its inception in 1994, the totally laparoscopic RYGB, though technically demanding, has become the procedure of choice for morbid obesity.¹⁸ The laparoscopic technique is associated with a decrease in complications and an improvement in quality-of-life.¹⁸ There are several variations to the technique, but all include

the creation of a small gastric reservoir, a gastro-jejunal anastomosis and a biliary limb and Roux-limb of varying lengths.

Sleeve gastrectomy (SG), originally performed as the restrictive component of the duodenal switch procedure,¹⁹ has recently been recognized as a valid option for the surgical treatment of morbid obesity.²⁰ In the past 10-years it has evolved from an investigational stand-alone procedure to ~5% of all bariatric surgeries.²¹ It usually is performed through a laparoscopic approach and involves the creation of a narrow tubular stomach due to a vertical gastrectomy based along the greater curvature.²² It has shown an intermediate result between gastric banding and RYGB in terms of weight loss, and an improvement in co-morbidities similar to that seen after RYGB.^{21,23,24}

Development of gastroesophageal reflux disease (GERD) is one of the most frequent complications of SG with up to 26% of patients experiencing new symptoms after surgery²⁵ and up to 30% requiring reoperation due to GERD or weight increase caused by dilatation of the gastric tube.^{26,27}

The evaluation of outcomes in bariatric surgery is of utmost importance, although it is not easy to do. There are several different risks at stake (including death) and different outcomes to be achieved: health related quality of life (QoL), weight loss and resolution of associated diseases. Several studies evaluating QoL measures have shown conflicting results.^{28–31}

Also, due to the technical nature of the procedures, small variations in the technique (such as pouch size, anastomoses diameter or limb lengths) or different techniques (RYGB, gastric band, SG, and others) being used by different surgeons and different centers makes it more difficult to analyze the results and compare data. Patient follow-up and reporting are usually sub-optimal and the parameters used to measure improvement or resolution of comorbidities have not been standardized.³² Many of the published studies are retrospective cohorts or case series rather than prospective randomized trials, and may not be truly representative of differences in QoL between different procedures. So, despite the more than 350,000 surgeries performed worldwide each year, we are still lacking consensus on which is the best surgery for each patient.³³

Obesity is associated with reduced QoL and in general, QoL improves after bariatric surgery.³⁴ The differential effect of each surgery on QoL is not yet fully understood, but it seems that RYGB is associated with better patient-centered outcome measures and greatest improvement in QoL.^{26,32,35}

Since SG numbers are increasing and the clinical results seem to be comparable to RYGB, at least in the short term, it is important to understand which of these surgeries offers greater improvement in QoL and patient satisfaction.

Materials and methods

We performed a systematic review of the literature, with the primary objective being to compare the quality of life of morbidly obese patients after RYGB and SG. A secondary focus was related to comparing weight loss and measures of alimentary satisfaction.

Literature search: We performed a systematic literature search on Pubmed in July 2014, with the following terms: ["patient satisfaction" or "quality of life" or "patient reported outcomes"] and ["gastric sleeve" or "gastric bypass" or "bariatric surgery" or "metabolic surgery"]. Since the MeSH thesaurus is not up to date, and several relevant papers were published in the latter year, we opted to use general language search. The search was restricted to humans and there was no date restriction nor any other restrictions to types of studies, participants or interventions. Only articles in English, Spanish, French or Portuguese were selected.

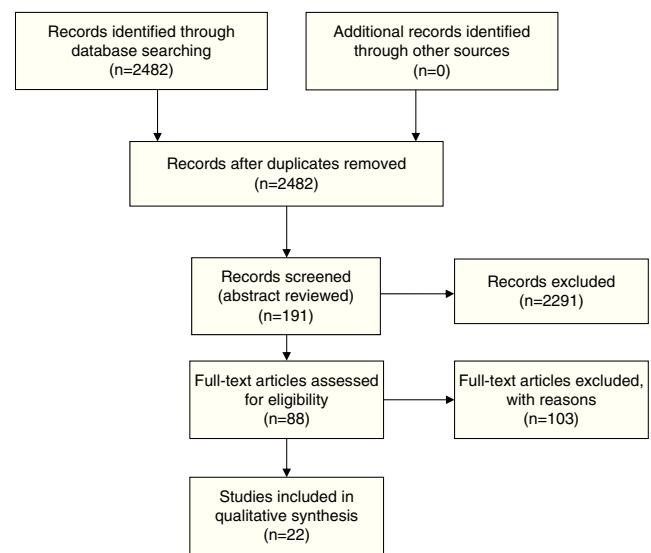

Fig. 1. Prisma flow diagram. From the 88 papers selected for full text revision, only 22 had retrievable objective data, which were used in the summary tables. Only 5 studies had a direct comparison between both techniques, 2 of which were randomized controlled trials.

Relevant articles were selected in a step-wise approach. The search retrieved 2482 titles that were scanned for relevance and 191 of these were selected for abstract reviewing. The abstracts were reviewed and 88 papers were selected for full text analysis (Fig. 1). Papers selection and reviewing was performed unblinded by the first author, based on relevance and the presence of retrievable (numeric) data in the full-text of the paper. Only papers that evaluated QoL after each intervention using validated QoL questionnaires were selected. Papers that mentioned "quality of life" but did not use any measure were excluded, as well as papers evaluating QoL in other types of surgery. Data was extracted from the papers in tables (Tables 1 and 2). Only 22 papers had retrievable data and were used in the analysis. One of the papers used the Food Tolerance Questionnaire, 3 used the M-A-II, 3 used the BAROS, 3 used the GIQLI and 13 used the SF-36.

Outcomes used

Many validated generic questionnaires can be used to assess QoL. The most frequently used questionnaire is the Short Form-36 (SF-36).³⁶ However, these instruments are often times exhaustive, might require interviewers and are not validated for follow-up of bariatric patients since they are not disease specific.³⁷ The condition specific Moorehead-Ardelt Quality of Life Questionnaire II³⁸ (MA-II, alone or integrated in the BAROS) is a simple, 1-page, valid, reliable, appropriate and reproducible instrument to assess patient's QoL before and after bariatric surgery. Since it uses pictures to represent different health states, it bridges linguistic, cultural and educational barriers.³⁷ However, both BAROS and MA-II are copyrighted, which might preclude their widespread use.

The Gastrointestinal Quality of Life Index (GIQLI) is a questionnaire capable of providing information on generic and specific aspects of digestive symptoms and QoL. For this reason, GIQLI has been extensively used in different pathologies and to evaluate medical treatments or surgical procedures performed on the digestive tract.

BAROS

The Bariatric Analysis and Reporting Outcome System was proposed in 1998.³⁹ It included analysis of weight loss, improvement in

co-morbidities and changes in QoL using the specifically designed Moorehead-Ardelt Quality of Life Questionnaire. Each of these 3 domains was granted up to 3 points and re-operations and complications deduct points. Thus, a scale from 0–9 points could be constructed. The outcomes were translated as ≤1 point – failure^{2,3}; fair^{4,5}; good^{6,7}; very good^{8,9}; excellent. This system has been one of the most widely used QoL instruments for bariatric surgery and allows direct comparison of results between centers or between different surgical techniques. It later incorporated the Moorehead-Ardelt Quality of Life Questionnaire II³⁸ and recently the updated BAROS II has been published,³⁷ which includes new criteria for diabetes and clarifies the concept of improvement.

Given its simplicity, BAROS is associated with better patient compliance than the longer, more generic SF-36.⁴⁰

However, many reports only present the aggregate results of the BAROS score and only in a single post-operative assessment. This greatly reduces understanding of the underlying behaviors related to success or failure of the procedure.

M-A Quality of Life Questionnaire II

M-A Quality of Life Questionnaire II has been validated as a tool to assess quality of life. The questionnaire is composed of six items

to measure the patient's quality of life in the areas of general self-esteem, physical activity, social contact, work satisfaction, sexuality and eating behavior. Points are added or deducted based on the patients' subjective perception. Each item is answered in a Likert-type 10 point scale, with variations from –0.5 to +0.5. It is simple, user friendly and can be completed within 1 min. The total score is the sum of six dimensions with a range of –3.0 to +3.0.³⁸

The MA-II was validated by a study³⁸ on RYGB patients, 90 women and 20 men, with a mean BMI of 50 kg/m². Cronbach's α coefficient of .84 demonstrated internal consistency and the instrument's reliability. The scores correlated significantly ($p < .01$) with 7 of the 8 scales of the SF-36 Health Survey. A literature review has concluded that from 11 questionnaires measuring obesity the MA-II seems to be the most promising.⁴¹

SF36

SF-36 is a generic health status questionnaire, developed to evaluate self-reported physical and mental health across a wide range of medical conditions.⁴⁰ It is an instrument studied and used in bariatric surgery, and is endorsed by the International Bariatric Surgery Registry.

RCT – randomized control trial. %EWL – percentage of excess weight lost.

^a Non surgical control group (not a longitudinal analysis).

n/r – not reported; n/a – not applicable. SF-36 – physical component score (SF36 scores in italic are raw data; all other values are normalized).

^b General Health question of SF-36.^c Only patients with T2DM.

Obesity has been correlated with lower scores, especially in the physical component of SF-36. Several trials of bariatric surgery have concluded that after surgery, there is an improvement in the SF-36 scores, and thus, this is a sensitive instrument to capture this construct.⁴⁰

In spite of lower pre-operative values associated with obesity, bariatric surgery patients with long-term follow-up seem to have SF-36 scores similar to the normal US⁴⁰ and Spanish population.⁴² Overall, SF-36 has been the patient reported outcome (PRO) measure most often reported.³⁶

GIQLI

Compared to other questionnaires, the GIQLI provides information on the quality of life of the patient in relation to both generic aspects (physical status, social relations, emotional status) and specific aspects of the upper and lower digestive tract. Also, it is a self-contained, easy-to-understand and easy-to-complete questionnaire that does not require much time to enter the data. It can assess the changes in quality of life of an obese patient who has undergone bariatric surgery (due to the changes caused in the intestinal tract by this type of surgery), and has been validated in this group of patients.⁴³

Several other questionnaires have been developed. However, since they have been scarcely used and there is no direct comparison for SG or RYGB, we opted not to include them in this analysis. The only exception was the report from Freeman et al.,⁴⁴ since it was one of the few studies with direct comparison between both techniques.

Results

Although the expression “quality of life” is intuitively understood by most people, there is not yet a comprehensive definition.⁴⁵ Quality of life is a construct of physical, psychological and social domains of health that can be measured by a series of questionnaires.⁴⁶ These measures can be influenced by a person's experiences, beliefs, expectations and perceptions. Generic instruments measure a wide array of health states, conditions and diseases, allowing for comparisons between disease states. Disease-specific instruments focus on the domains most relevant to the disease under study and might be more sensitive to detect changes due to interventions.⁴⁶

Of the 88 papers selected for reviewing, only 5 papers compared RYGB and SG (**Table 1**), and only 17 more had retrievable data and could be thoroughly analyzed (**Table 2**). The reports were very heterogeneous, preventing a direct comparison of PRO between studies. Not only were the populations different, but also there were a wide variety of instruments used. Even if the same instruments were used, there was no uniform reporting of the results. Several studies only showed aggregate results, others did not show results at all (only stating that QoL was improved) and some presented graphs with no significant legends. Furthermore, some studies with complete patient outcomes reporting did not have information about which type of surgery had been done and how. The great majority of studies analyzed outcomes at one time-point alone, thus limiting the interpretation of the measure of change.

A recently published RCT⁴⁷ concluded that the 1 year QoL was significantly improved after both SG and RYGB ($p < .001$ from baseline) and was even higher than in healthy individuals (GIQLI 127 & 128 vs 121; $p < .01$). At the end of the first post-operative year there were no significant differences between groups (SG vs RYGB) either in terms of weight loss, resolution of co-morbidities or GIQLI scores. For the patients who had reached the 3rd follow-up year there was a small and not statistically significant difference in weight loss,

favoring patients with RYGB (% excess BMI lost 63.3% vs 72.8%; $p = \text{NS}$).

Mohos et al.,²⁶ in a BMI matched analysis, concluded that there is a significant improvement in weight loss and QoL after both types of surgery, but the results seem better after RYGB (although the follow-up period is greater for SG and there is no baseline analysis of the QoL). Again, both groups of patients achieved aggregate SF-36 scores similar to the normal population.

It was also reported that decreased food tolerance was associated with a reduced GIQLI, thus impacting the overall QoL.⁴⁸ A direct comparison between SG and RYGB (although with shorter follow-up for SG) shows a non-significant difference in the GIQLI score in favor of SG (120.5 vs 113.0).⁴⁸

A 2013 meta-analysis conducted by Yang et al.⁴⁹ comparing the clinical outcomes between SG and RYGB could analyze only 8 papers, 6 of which were RCT's. According to this meta-analysis, RYGB has higher weight loss than SG, but no information of patient reported outcomes is given.

Improvement in the physical domains of QoL have been reported as early as 3 months after RYGB.⁵⁰

A study in Brazil concluded that after RYGB, the short-term effects (1 year) were stronger than those achieved at 7-years follow-up, both in terms of QoL and weight loss, with an increase in BMI of 6 kg/m^2 between these time-periods.⁵¹

A large cohort of RYGB patients analyzed by Al Harakeh⁵² reported significant improvement in BAROS scores at almost all time-points (3 weeks to 5 years). The results were better at 18 months and were slightly more positive in women and in patients with lower baseline BMI. Since baseline values were not presented, these patients may have different baseline values.

A small study from New Zealand concluded that 6 months after both SG and RYGB, SF-36 component summary scores were comparable to the average population.⁵³ Pristed et al.⁴⁵ reported that QoL 12 months after surgery in a cohort of 87 RYGB patients was not different from the national norm. A long-term study by de Zwaan et al.⁵⁴ with 13 years of follow-up concludes the same: compared to the pre-operative group, patients who had RYGB present values close to the reference of the population. Kolotkin et al.⁵⁵ report an improvement of 1.17SD in the physical component score of the SF-36 at 6 years after RYGB. This effect was greatest at the 2nd post-operative year and slightly decreased at 6 years.

A recent report by Halperin et al.⁵⁶ in patients with type 2 diabetes concluded that even though cardiometabolic risk factors and weight improvement were better after gastric bypass than optimized lifestyle intervention, the 12 months SF-36 scores were not different between the groups. However, the more disease-specific IWQOL revealed a significant improvement in obesity related QoL (81.7–46.5; $p < 0.001$) after gastric bypass.

After SG, QoL is improved in most patients and scales used. In a group of patients primarily treated for obesity associated T2DM, SF-36 was improved in every domain⁵⁷ at 6 months after surgery. One year after SG, non-selected patients reported significant improvements in all the SF-36 measures.^{58–60}

Long-term follow up of the SOS study concluded that 10 years after bariatric surgery, large groups of patients started to regain weight. However, a long-term weight loss of ~10% was enough for positive long-term effects on QoL.⁵

Discussion

Empirical data has suggested that subjects with morbid obesity might experience worse QoL than normal-weight subjects, including symptoms of psychological discomfort since many areas of their everyday life are adversely affected (including inter-personal relations).⁶¹ However, the major impact of obesity on QoL has

been reported in the physical dimensions.⁴² Obese individuals were more likely to report poor health, increased unhealthy days caused by physical or mental problems and increased total unhealthy days per month.⁴⁰ Although obesity has been associated with a decreased QoL,⁴⁰ several studies report that there is no linear relation between higher BMI's and lower QoL.⁶²

Patients with morbid obesity who seek bariatric surgery seem to have lower QoL scores,⁶³ and bariatric surgery improves QoL.⁴⁰ The clinical effectiveness regarding weight loss and resolution of co-morbidities in the long-term seems to favor RYGB.^{49,64}

In spite of its importance, weight loss is not the only measure of success of bariatric surgery. Quality of life parameters and patient satisfaction are increasingly recognized as important measures. The first report of patient satisfaction after bariatric surgery dates back to 1983 and here, Hall⁶⁵ concludes that satisfaction was associated with improved health, better self-image and greater social activity. Also, satisfaction increased with weight loss and decreased with unrealistic expectations.

Improved results have been reported as early as 3 months⁵⁰ and SF-36 scores were improved in all domains in medium to long-term follow up of RYGB patients.^{42,55,66–68}

Unfortunately, most studies that evaluate QoL only present the global satisfaction level of the patients, and there are few studies comparing baseline with post-operative scores. Furthermore, a 2013 systematic review of PRO in bariatric surgery identified 68 different PRO measures, which prevents direct comparisons.³⁶

Some authors⁵ have concluded that a modest weight loss was associated with significant effect on quality of life. In spite of greater weight loss after RYGB, one study concluded that the QoL after gastric band or RYGB was the same.⁶⁹

Long-term (5 years) studies with high follow-up rates,⁶⁶ have concluded that both weight loss and QoL improvement are sustained. Most studies, however, report short-term evaluations or have low follow-up rates.

Larger effect sizes have been reported in the physical dimensions of the QoL questionnaires.⁵⁹ This might be explained by the reduction of body pain, increased stamina and physical activity, and improvements in shortness of breath and foot problems.⁵⁹

Some reports conclude that improvement in QoL is related to weight loss and improvement of the co-morbidities.^{57,59,70–72} In a population based cohort study, Batsis⁷² concluded that the self-reported QoL after surgery could be predicted by a profound weight loss and by the absence of co-morbidities. Improved patient satisfaction (which is a different construct from QoL) has also been reported in association with increasing weight loss.⁷³

The relation between QoL and weight loss is difficult to interpret, since it appears not to be linear^{42,74} and other reports concluded that improvement in QoL occurred early on and was not correlated with weight loss.^{50,58} Kolotkin et al.⁵⁵ concluded that the weight loss accounted for only 28.5% of the variance in the physical component score of the SF-36. D'Hondt,⁷⁵ reported that 6 years after SG the physical components of the SF-36 were higher in the patients that had >50% of EWL. The recent randomized control trial comparing RYGB with intensive lifestyle intervention⁵⁶ in type 2 diabetes patients concluded that in both groups, the weight-specific quality-of-life improvements (as measured by IWQOL) were proportional to weight lost.

On the other hand, QoL measures might be correlated not with weight loss, but with fulfillment of patients' expectations.⁴⁵ Even for patients that remained morbidly obese, RYGB has been reported to have a positive effect on QoL.^{66,68} According to Testa and Simonson, two individuals with the same health status may report different health related QoL because of differences in their expectations and ability to cope with expectations.⁴⁶

Specifically in bariatric surgery patients, the expectations are often times high and unrealistic, which might impact on the QoL reported.⁴⁵ The improvement in the emotional QoL domains might be related to an improved perception of self, related to weight loss.⁵⁹

Klingemann⁷⁴ reports that it is not the amount of weight lost that is related to the QoL, but rather the achieved BMI and Sarwer⁷⁰ suggests that body image and QoL were directly correlated.

Al Harakeh⁵² concluded that BAROS scores were higher in women and in patients with lower BMIs, which raises the question of comparison between different studies that have different distributions of participants. Reports from Sarwer et al.⁷⁰ and Leiva et al.⁷⁶ also concluded that QoL improvement was greater in higher educated patients.

Furthermore, Fezzi⁵⁸ concluded that surgical complications were not associated with the improvement of the physical domain QoL measures, but a smaller percentage of patients achieved significant improvements in the psychological domains. Patients with psychiatric disorders and depression are not able to achieve QoL comparable to the population norm,^{77,78} which confirms that the emotional and psychological domains also influence the overall results.

The GIQLI score is most sensitive for measuring gastrointestinal symptoms. Although the mean scores improved after RYGB,⁷⁹ some patients developed new symptoms, mainly related to vomiting, slow eating and abdominal discomfort.

Food tolerance and diet quality might also be related to increased perceptions of QoL. The definition of good food tolerance has been proposed to be the ability to consume a variety of foods without difficulty and with minimal regurgitation/vomiting,⁸⁰ and seem to be different according to the type of surgery and the time elapsed.^{44,80,81} SG and RYGB had results comparable to the baseline population in terms of overall food tolerance and increased satisfaction with eating.⁴⁴ Increase food quality was also associated with "healthier" food choices, which might help to explain its association with increased weight loss.

So, the question remains whether the improvement in QoL is related to the weight loss and which factors are associated with increased patients' perceptions. Also, it is not clear if there are specific aspects in the QoL that are related to each type of surgery.

Conclusions

There is wide heterogeneity in the reporting of PRO measures after bariatric surgery, but the data are consistent with a significant improvement after both types of surgeries. The improvement starts within the first few months after the surgery and lasts up to 10 years. Obese patients present lower values of QoL, but generally 1 year after the surgery are indistinguishable from the general population. The few studies that compared QoL between RYGB and SG could not detect any significant difference.

Larger and better-designed studies are required in order to understand if there are significant differences in the quality of life after SG or RYGB. The development of computer assisted dynamic tools might help achieving greater discrimination in the evaluation of obesity related QoL.
